Abstract

Contemporary workflow management systems are driven by explicit process models, i.e., a completely specified workflow design is required in order to enact a given workflow process. Creating a workflow design is a complicated time-consuming process and typically there are discrepancies between the actual workflow processes and the processes as perceived by the management. Therefore, we propose a technique for rediscovering workflow models. This technique uses workflow logs to discover the workflow process as it is actually being executed. The workflow log contains information about events taking place. We assume that these events are totally ordered and each event refers to one task being executed for a single case. This information can easily be extracted from transactional information systems (e.g., Enterprise Resource Planning systems such as SAP and Baan). The rediscovering technique proposed in this paper can deal with noise and can also be used to validate workflow processes by uncovering and measuring the discrepancies between prescriptive models and actual process executions.

1. Introduction

During the last decade workflow management concepts and technology [2,17,20] have been applied in many enterprise information systems. Workflow management systems such as Staffware, IBM MQSeries, COSA, etc. offer generic modeling and enactment capabilities for structured business processes. By making graphical process definitions, i.e., models describing the life-cycle of a typical case (workflow instance) in isolation, one

can configure these systems to support business processes. Besides pure workflow management systems many other software systems have adopted workflow technology. Consider for example ERP (Enterprise Resource Planning) systems such as SAP, PeopleSoft, Baan and Oracle, CRM (Customer Relationship Management) software, etc. Despite its promise, many problems are encountered when applying workflow technology. As indicated by many authors, workflow management systems are too restrictive and have problems dealing with change [2,3,5,10,18]. Many workshops and special issues of journals have been devoted to techniques to make workflow management more flexible (e.g., [2,3,18]). Most of the research in this area is devoted to techniques to increase the flexibility either by allowing for ad-hoc changes (as reflected by workflow management systems such as InConcert [16]) or by providing mechanisms to migrate cases and evolve workflows [5,10].

In this paper we take a different perspective with respect to the problems related to flexibility. We argue that many problems are resulting from a discrepancy between workflow *design* (i.e., the construction of predefined workflow models) and workflow *enactment* (the actual execution of workflows). Workflow designs are typically made by a small group of consultants, managers and specialists. As a result, the initial design of a workflow is often incomplete, subjective, and at a too high level. During the implementation of the workflow, i.e., configuring the workflow management system and training the workers involved, these issues cause many problems (“The devil is in the details”). Therefore, we propose to “reverse the process”. Instead of starting with a workflow design, we start by gathering information about the workflow processes as they take place. We assume that it is possible to record events such that (i) each event refers to a task (i.e., a well-defined step in the workflow), (ii) each event refers

to a case (i.e., a workflow instance), and (iii) events are totally ordered. Any information system using transactional systems such as ERP, CRM, or workflow management systems will offer this information in some form. Note that we do not assume the presence of a workflow management system. The only assumption we make, is that it is possible to construct workflow logs with event data. These workflow logs are used to construct a process specification, which adequately models the behavior registered. We use the term *process mining* for the method of distilling a structured process description from a set of real executions. In this paper, we propose a new technique for process mining.

The remainder of this paper is as follows. First we discuss related work. Section 3 introduces some preliminaries including a modeling language for workflow processes and the definition of a workflow log. Then we present a new technique for process mining. Finally, we conclude the paper by summarizing the main results and pointing out future work.

2. Related work

The idea of process mining is not new [4,6,7,8,12,13,14,15,19]. Cook and Wolf have investigated similar issues in the context of software engineering processes. In [6] they describe three methods for process discovery: one using neural networks, one using a purely algorithmic approach, and one Markovian approach. The authors consider the latter two the most promising approaches. The purely algorithmic approach builds a finite state machine where states are fused if their futures (in terms of possible behavior in the next k steps) are identical. The Markovian approach uses a mixture of algorithmic and statistical methods and is able to deal with noise. Note that the results presented in [6] are limited to sequential behavior. Cook and Wolf extend their work to concurrent processes in [7]. They also propose specific metrics (entropy, event type counts, periodicity, and causality) and use these metrics to discover models out of event streams. This approach is similar to the one presented in this paper. However, our metrics are quite different and our final goal is to find explicit representations for a broad range of process models, i.e., we generate a concrete Petri net rather than a set of dependency relations between events. In [8] Cook and Wolf provide a measure to quantify discrepancies between a process model and the actual behavior as registered using event-based data.

The idea of applying process mining in the context of workflow management was first introduced in [4]. This work is based on workflow graphs, which are inspired by workflow products such as IBM MQSeries workflow (formerly known as Flowmark) and InConcert. In this paper, two problems are defined. The first problem is to find a workflow graph generating events appearing in a given workflow log. The second problem is to find the definitions of edge conditions. A concrete algorithm is given for tackling the first problem. The approach is quite different from the approach presented in this paper. Given the nature of workflow graphs there is no need to identify the nature (AND or OR) of joins and splits. Moreover, workflow graphs are acyclic. The only way to deal with iteration is to enumerate all occurrences of a given activity. In [19], a tool based on these algorithms is presented.

Herbst and Karagiannis also address the issue of process mining in the context of workflow management [12,13,14,15]. The approach uses the ADONIS modeling language and is based on hidden Markov models where models are merged and split in order to discover the underlying process. The work presented in [12,14,15] is limited to sequential models. A notable difference with other approaches is that the same activity can appear multiple times in the workflow model. The result in [13] incorporates concurrency but also assumes that workflow logs contain explicit causal information. The latter technique is similar to [4,19] and suffers from the drawback that the nature of splits and joins (i.e., AND or OR) is not discovered.

Compared to existing work we focus on workflow processes with concurrent behavior, i.e., detecting concurrency is one of our prime concerns. Therefore, we want to distinguish AND/OR splits/joins explicitly. To reach this goal we combine techniques from machine learning with WorkFlow nets (WF-nets, [1]). WF-nets are a subset of Petri nets. Note that Petri nets provide a graphical but formal language designed for modeling concurrency. Moreover, the correspondence between commercial workflow management systems and WF-nets is well understood [1,2,11,17,20].

3. Preliminaries: Workflow nets and event logs

Workflows are by definition *case-based*, i.e., every piece of work is executed for a specific *case*. Examples of cases are a mortgage, an insurance claim, a tax declaration, an order, or a request for information. The goal of workflow management is

to handle cases as efficient and effective as possible. A workflow process is designed to handle similar cases. Cases are handled by executing *tasks* in a specific order. The workflow process model specifies which tasks need to be executed and in what order. Alternative terms for such a model are: ‘procedure’, ‘workflow graph’, ‘flow diagram’ and ‘routing definition’. In the workflow process model, routing elements are used to describe sequential, conditional, parallel and iterative routing thus specifying the appropriate route of a case [17,20]. Many cases can be handled by following the same workflow process definition. As a result, the same task has to be executed for many cases.

Petri nets [9] have been proposed for modeling workflow process definitions long before the term “workflow management” was coined and workflow management systems became readily available. Consider for example the work on Information Control Nets, a variant of the classical Petri nets, in the late seventies [11]. Petri nets constitute a good starting point for a solid theoretical foundation of workflow management. Clearly, a Petri net can be used to specify the routing of cases (workflow instances). *Tasks* are modeled by *transitions* and *places* and *arcs* model *causal dependencies*. As a working example we use the Petri net shown in Figure 1.

Figure 1: example of a workflow process modeled as a Petri net.

The transitions $T1, T2, \dots, T13$ represent tasks. The places $Sb, P1, \dots, P10, Se$ represent the causal dependencies. In fact, a place corresponds to a condition that can be used as pre- and/or post-condition for tasks. An AND-split corresponds to a transition with two or more output places (from $T2$ to $P2$ and $P3$), and an AND-join corresponds to a transition with two or more input places (from $P8$ and $P9$ to $T11$). OR-splits/OR-joins correspond to places with multiple outgoing/ingoing arcs (from $P5$ to $T6$ and $T7$, and from $T7$ and $T10$ to $P8$). At any time a place contains zero or more *tokens*, drawn as black dots. Transitions are the active components in a Petri net: they change the state of the net according to the following *firing rule*:

- (1) A transition t is said to be *enabled* iff each input place of t contains at least one token.
- (2) An enabled transition may fire. If transition t fires, then t consumes one token from each input place p of t and produces one token for each output place p of t .

A Petri net which models the control-flow dimension of a workflow, is called a *Workflow net* (WF-net) [1]. A WF-net has one source place (Sb) and one sink place (Se) because any case (workflow instance) handled by the procedure represented by the WF-net is created when it enters the workflow management system and is deleted once it is completely handled, i.e., the WF-net

specifies the life-cycle of a case. An additional requirement is that there should be no “dangling tasks and/or conditions”, i.e., tasks and conditions which do not contribute to the processing of cases. Therefore, all the nodes of the workflow should be on some path from source to sink.

The WF-net focuses on the process perspective and abstracts from the functional, organization, information and operation perspectives [17]. These perspectives can be added using for example high-level Petri nets, i.e., nets extended with color (data) and hierarchy. Although WF-nets are very simple, their expressive power is impressive. In this paper we restrict our self to so-called *sound* WF-nets [1]. A workflow net is sound if the following requirements are satisfied: (i) termination is guaranteed, (ii) upon termination, no dangling references (tokens) are left behind, and (iii) there are no dead tasks, i.e., it should be possible to execute an arbitrary task by following the appropriate route. Soundness is the minimal property any workflow net should satisfy. Note that soundness implies the absence of live locks and deadlocks. Sound WF-nets can be used to model the basic constructs identified by the Workflow Management Coalition [20] and used in contemporary workflow management systems. Experience with leading workflow management

systems such as Staffware, COSA, MQSeries Workflow, etc. show that it is fairly straightforward to express these tool-specific languages in terms of the tool-independent language of WF-nets. For an introduction to WF-nets the reader is referred to [1].

In this paper, we use *workflow logs* to discover workflow models expressed in terms of WF-nets. A workflow log is a sequence of *events*. Each event is described by *case identifier* and a *task identifier*. An event $e=(c,t)$ corresponds to the execution of task t for a given case c . For reasons of simplicity we assume that there is just one workflow process. Note that this is not a limitation since the case identifiers can be used to split the workflow log into separate workflow logs for each process. One workflow log may contain information about thousands of cases. Since there are no causal dependencies between events corresponding to different cases, we can project the workflow log onto a separate event sequence for each case without losing any information. Therefore, we can consider a workflow log as a set of event sequences where each event sequence is simply a sequence of task identifiers. Formally, $WL \subseteq T^*$ where WL is a workflow log and T is the set of tasks. An example event sequence of the Petri net of Figure 1 is given below:

$T1, T2, T4, T3, T5, T9, T6, T3, T5, T10, T8, T11, T12, T2, T4, T7, T3, T5, T8, T11, T13$

Using the definitions for WF-nets and event logs we can easily describe the problem addressed in this paper: Given a workflow log WL we want to discover a WF-net that (i) potentially generates all event sequence appearing in WL , (ii) generates as few event sequences of $T^* \setminus WL$ as possible, (iii)

captures concurrent behavior, and (iv) is as simple and compact as possible. Moreover, to make our technique practical applicable we want to be able to deal with noise.

4. Process mining technique

In this section we present the details of our process mining technique. We can distinguish three mining steps: Step (i) the construction of a dependency/frequency table (D/F-table), Step (ii) the induction of a D/F-graph out of a D/F-table, and Step (iii) the reconstruction of the WF-net out of the D/F-table and the D/F graph.

4.1 Construction of the dependency/frequency table

The starting point of our workflow mining technique is the construction of a D/F-table. For each task A the following information is abstracted out of the workflow log: (i) the overall frequency of task A (notation $\#A$), (ii) the frequency of task A directly preceded by another task B (notation $B<A$), (iii) the frequency of A directly followed by another task B (notation $A>B$), (iv) the frequency of A directly or indirectly preceded by another task B but before the previous appearance of A (notation $B<<<A$), (v) the frequency of A directly or indirectly followed by another task B but before the next appearance of A (notation $A>>>B$), and finally (vi) a metric that indicates the strength of the causal relation between task A and another task B (notation $A \rightarrow B$).

	#B	B<A	A>B	B<<<A	A>>>B	A → B
T10	1035	0	581	348	1035	0.803
T5	3949	80	168	677	897	0.267
T11	1994	0	0	528	1035	0.193
T13	1000	0	0	0	687	0.162
T9	1955	50	46	366	538	0.161
T8	1994	68	31	560	925	0.119
T3	3949	146	209	831	808	0.019
T6	1035	0	0	348	348	0.000
T7	959	0	0	264	241	-0.011
T12	994	0	0	528	505	-0.093
T1	1000	0	0	687	0	-0.246
T2	1994	0	0	1035	505	-0.487
T4	1994	691	0	1035	505	-0.825

Table 1: an example D/F-table for task $T6$ with. For an explanation of the notations (i) $\#A$, (ii) $B<A$, (iii) $A>B$, (iv) $B<<<A$, (v) $B<<<A$, and (vi) $A \rightarrow B$ we refer to subsection 4.1.

Metric (i) through (v) seems clear without extra explanation. The underlying intuition of metric (vi) is as follows. If it always the case that, when task A occurs, shortly later task B also occurs, then it is plausible that task A causes the occurrence of task B . On the other hand, if task B occurs (shortly) before task A it is implausible that task A is the cause of task B . Below we define the formalization of this intuition. If, in an event stream, task A occurs before task B and n is the number of intermediary events between them, the $A \rightarrow B$ -causality counter is incremented with a factor (d^n). d is a causality fall factor (d in $[0.0 \dots 1.0]$). In our experiments d is set to 0.8. The effect is that the contribution to the causality metric is maximal 1 (if task B appears directly after task A then $n=0$) and decreases if the distance increases. The process of looking forward from task A to the occurrence of task B stops after the first occurrence of task A or task B . If task B occurs before task A and n is again the number of intermediary events between them, the $A \rightarrow B$ -causality counter is decreased with a factor (d^n). After processing the whole workflow log the $A \rightarrow B$ -causality counter is divided by the overall frequency of task A ($\#A$).

Given the process model of Figure 1 a random workflow log with 1000 event sequences (23573 event tokens) is generated. As an example Table 1 shows the above-defined metrics for task $T6$. Notice that the task $T6$ belongs to one of two concurrent event streams (the AND-split in $T2$). It can be seen from Table 1 that (i) only the frequency of $T6$ and $T10$ are equal ($\#T6=\#T10=1035$), (ii) $T6$ is never directly preceded by $T10$ ($B < A = 0$), (iii) $T6$ is often directly followed by $T10$ ($A > B = 581$), (iv) $T6$ is sometimes preceded by $T10$ ($B < < A = 348$), and (v) always preceded by $T10$ ($A > > B = \#T6 = 1035$). Finally, (vi) there is strong causality relation from $T6$ to $T10$ (0.803) and to a certain extent to $T5$ (0.267). However, $T6$ is from time to time directly preceded by $T5$ ($B < A = 80$). In the next section we will use the D/F-table in combination with a relatively simple heuristic to construct a D/F-graph.

4.2 Induction of dependency/frequency graphs

In the previous section we observed that the information in the $T6$ -D/F-table strongly suggests that task $T6$ is the cause for task $T10$ because the causality between $T6$ and $T10$ is high, and $T6$ is never directly preceded by $T10$ and frequently

(directly) followed by $T10$. Our first heuristic rule is in line with this observation:

$$\text{IF } ((A \rightarrow B \geq N) \text{ AND } (A > B \geq S) \text{ AND } (B < A \leq S)) \text{ THEN } \langle A, B \rangle \hat{I} T \quad (1)$$

The first condition ($A \rightarrow B \geq N$) uses the noise factor N (default value 0.05). If we expect more noise we can increase this factor. The first condition calls for a higher positive causality between task A and B than the value of the noise factor. The second condition ($A > B \geq S$) contains a threshold value S . If we know that we have a workflow log that is totally noise free, then every task-patron-occurrence is informative. However, to protect our induction process against inferences based on noise, only task-patron-occurrences above a threshold frequency S are reliable enough for our induction process. To limit the number of parameters the value S is automatically calculated using the following equation: $S = 1 + \text{Round}(N * \#L / \#T)$. N is the noise factor, $\#L$ is the number of trace lines in the workflow log, and $\#T$ is the number of elements (different tasks) in the node set T . In our working example $S = 1 + \text{Round}(0.05 * 1000 / 13) = 5$. It is clear now that the second condition demands that the frequency of $A > B$ is equal or higher than the threshold value S . Finally, the third condition states the requirement that the frequency of $B < A$ is equal or higher than S . Applying this simple rule on the D/F-table based on the Figure 1 workflow-log results in the D/F-graph of Figure 2. If we compare the D/F-graph of Figure 2 with the Petri net of Figure 1 it can be seen that all the connections between the nodes are in accordance with underlying workflow model (all connections are correct and there are no missing connections).

However, the heuristic rule formulated above will not recognize recursion (in Figure 1, move the $T9$ - $P2$ arrow to $P6$) or short loops (in Figure 1, move the $T9$ - $P2$ arrow to $P4$). After all, the recursion in $T9$ will result in patterns like $T5, T4, T9, T9, T6, T9, T8$. Because $T9$ seems both cause for, and result from $T9$ the frequency of the casualty relation $T9 \rightarrow T9$ is about zero. However we can recognize the recursion relatively simple: it will result in both a high and equal frequency of $T9 > T9$ and $T9 < T9$ and a high and equal frequency of $T9 > > T9$ and $T9 < < T9$.

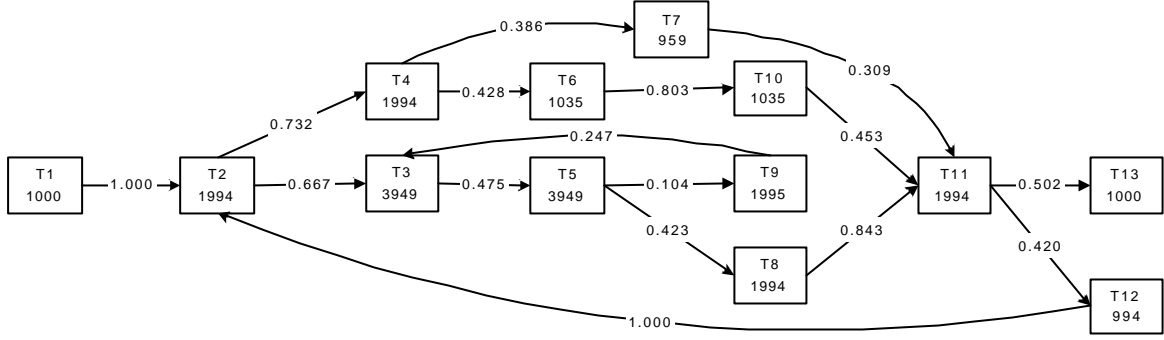

Figure 2: the automatically mined D/F-graph.

The short loop from $T9$ to $T5$ will result in patterns like $T5, T4, T9, T5, T9, T6, T5, T8$. Again $T5$ seems both cause for, and result from $T9$. However, short loops can be recognized by observing that both a high and about equal frequency of $T5 > T9$ and $T9 < T5$ and a high and about equal frequency of $T5 >> T9$ and $T9 <<< T5$. In line with this observations our first heuristic rule (1) is extended with rule (2) and (3):

IF $((A \rightarrow B \gg 0) \text{ AND } (A < A + A > A > 0.5 * \#A) \text{ AND } (A < A - A > A \gg 0))$
THEN $\langle A, A \rangle \hat{I} T (2)$

IF $((A \rightarrow B \gg 0) \text{ AND } (A > B \approx 0.4 * \#A) \text{ AND } (B < A \gg A > B) \text{ AND } (A >>> B \approx 0.4 * \#A) \text{ AND } (B <<< A \gg A >>> B))$
THEN $\langle A, B \rangle \hat{I} T (3)$

To prevent our heuristic from breaking done in the case of some noise, we use an about symbol (\approx) instead of the equality symbol ($=$). Again, the noise factor N is used to specify what we mean with ‘about equal’: $x \approx y$ iff the relative difference between them is less than N .

4.3 Generating WF-nets from D/F-graphs

Given a workflow log it appears relatively simple to find the corresponding D/F-graphs. But, the types of the splits and joins are not yet represented in the D/F-graph. However (i) information in the D/F-table, (ii) the frequency of the nodes in the D/F-graph, and (iii) the causality labels contain useful information to indicate the type of a join or a split.

For instance, if we have to detect the type of a split from A to B AND/OR C , we can look in the D/F-table to the values of $B > C$ and $B < C$. If A is an AND-split we expect a positive value for both $B > C$ and $B < C$ (because the pattern B, C and the pattern C, B can appear). If it is a OR-split the patterns B, C and C, B will not appear.

As an example of (ii) we look to the frequency of the nodes in the D/F-graph of Figure 2. $T2$ is an

AND-split (because $\#T4 = \#T2$ and there are no other incoming arcs for $T4$). $T5$ is an OR-split (because $\#T5 = \#T8 + \#T9$), and analogue $T4$ and $T11$. The join in node $T11$ is a little bit more complex: it appears a combination of a OR-join between $T7$ and $T10$, combined with a AND-join with $T8$ ($\#T7 + \#T10 = \#T8 = \#T11$).

As an example of (iii) compare the values from the AND-split in $T2$ (0.667 and 0.732) and the values from the OR-split in $T4$ (0.428 and 0.386). Relatively high values indicates an AND-split, relatively low values an OR-split. Analogue observations can be made for joins.

The pseudo code for an algorithm based on the first heuristic (i) is given in Table 2. Suppose, task A is directly preceded by the task B_1 to B_n . Set_l to Set_n are empty sets. After applying the algorithm all OR-related tasks are collected in a set Set_i . All not empty sets are in the AND-relation.

```

For i:=1 to n do
Begin
  For j:=1 to n do
  Begin
    OK:=False;
    Repeat
      If " $X \hat{I} Set_j [(B_i > X < \mathcal{S}) \text{ AND } (X > B_i < \mathcal{S})]$ " then
        Begin
           $Set_j := Set_j \hat{E} \{B_i\}$ ; OK:=True;
        End;
      Until OK;
    End j do;
  End i do;

```

Table 2: the pseudo code used to reconstruct the types of the splits and joins of a D/F-graph.

We can apply an analogue algorithm to reconstruct the type of a join. For instance, applying the algorithm on the $T11$ -join will result in two sets $\{T7, T10\}$ and $\{T8\}$ or in prepositional format $((T7 \text{ OR } T10) \text{ AND } T8)$. Using the algorithm of Table 2 we were able to reconstruct the types of the splits

and joins appearing in our working example and to reconstruct the complete underlying WF-net. In the next section we will report our experimental results of applying the above-defined heuristics on other workflow logs, with and without noise.

4.4 Experiments

To test our approach we use the Petri-net-representations of six different free-choice workflow models. The complexity of these models range from comparable with the complexity of our working model of Figure 1 (13 tasks) to models with 16 tasks. All models contain concurrent processes and loops. For each model we generated three random workflow logs with 1000 event sequences: (i) a workflow log without noise, (ii) one with 5% noise, and (iii) a log with 10% noise. Below we explain what we mean with noise.

To incorporate noise in our workflow logs we define four different types of noise generating operations: (i) delete the head of a event sequence, (ii) delete the tail of a sequence, (iii) delete a part of the body, and finally (iv) interchange two random chosen events. During the deletion-operations minimal one event, and maximal one third of the sequence is deleted. The first step in generating a workflow log with 5% noise is a normal random generated workflow log. The next step is the random selection of 5% of the original event sequences and applying one of the four above described noise generating operations on it (each noise generation operation with an equal chance of 1/4).

Due to lack of space it is not possible to describe all workflow models and the resulting D/F-graphs in detail. However, applying the above method on the six noise free workflow logs results in six perfect D/F-graphs (i.e. all the connections are correct and there are no missing connections), and exact copies of the underlying WF-nets. If we add 5% noise to the workflow logs, the resulting D/F-graphs and WF-nets are still perfect. However, if we add 10% noise to the workflow logs one D/F-graph is still perfect, five D/F-graphs contains one error. All errors are caused by the low threshold value $\sigma=5$ in rule (1), resulting in an unjustified applications of this rule. If we increase the noise factor value to a higher value ($N=0.10$), the automatically calculated threshold value σ increases to 9 and all five errors disappear and no new errors occur.

5. Conclusion

In this paper we (i) introduced the context of workflow processes and process mining, (ii) some

preliminaries including a modeling language for workflow processes, and (iii) a definition of a workflow log. Hereafter, we presented the details of the three steps of our process mining technique: Step (i) the construction of the D/F-table, Step (ii) the induction of a D/F-graph out of a D/F-table, and Step (iii) the reconstruction of the WF-net out of the D/F-table and the D/F graph.

In the experimental section we applied our technique on six different sound workflow models with about 15 tasks. All models contain concurrent processes and loops. For each workflow model we generated three random workflow logs with 1000 event sequences: (i) without noise, (ii) with 5% noise, and (iii) with 10% noise. Using the proposed technique we were able to reconstruct the correct D/F-graphs and WF-nets. The experimental results of the experiments with the workflow logs with noise indicate that our technique seems robust in case of noise.

Notwithstanding the reported results there is a lot of future work to do. First, the reported results are based on a limited number of experimental results; more experimental work must be done. Secondly, we will try to improve the quality and the theoretical basis of our heuristics. Can we for instance *prove* that our heuristic is successful applicable to logs from for instance free-choice WF-nets? Finally, we will extend our mining technique in order to enlarge the set of underlying WF-nets that can be successfully mined.
